### Abstract

Electric powered vehicles (EV's) and hybrid EV's is the next gen mobility ,Performance is a very crucial part where power capacity is restricted. Adding to its excessive balance and occasional price, To improve more efficiency and reduce the losses the induction motor is the best choice. This draws more power than the required when compared to maximum load. This made us to propose a method to control motor primarily based on the fuzzy logic manipulate for EV programs. This controller can enhance the starting cutting-edge amplitude and saves extra energy. Through the Simulation software like MATLAB/Simulink the overall performance of the system is manipulated and tested using the software. When compared to the traditional proportional imperative derivative controller, the schemes shows us the results and high-overall performance values in time-domain reaction and the fast rejection of device leads to disturbances. Thus the losses of the induction motor are substantially decreased, with this it improves the performance of the running device. The device is validated by means of the experimental situations obtained within the lab, Thus simulation outcomes are good.

**Keywords:** EV drive , Induction Motor , Fuzzy Logic Control.

### 1. Introduction

In last few decades, The usage of fuels increased a lot which led to increase in concentration of co2 in the atmosphere. Concerns approximately weather alternate and growing sea tiers as a result of international rise in temperature are becoming a big issue and looking for a way to reduce co2. A giant development within the fuel performance of automobiles is vital, because the production units emit 25% of total carbon dioxide emissions. Electric cars (EV's) have a lot of benefits because they are green, environment friendly, quiet, and commonly lesser power dependence than the selection of the electrical system. This leads to reduce the performance and the force available. But, machines are the main source for an force which include people who may be using EV's and hybrid EV's. The synchronous vehicles and induction automobiles (IMS) are the primary set of machines that can be used in Electric vehicles. The motor used to run the electric vehicle should have the characteristics of below.

- (i) High torque for better driving feel;
- (ii) Efficient for driving and increate speed, range.

### 2. Theoretical Analysis

In this, An FLC-based method is proposed for electric vehicles. A contrast among each of the controllers (PID and FLC) is then supplied based on their impact on IM performance. The principle contributions because of this paintings can

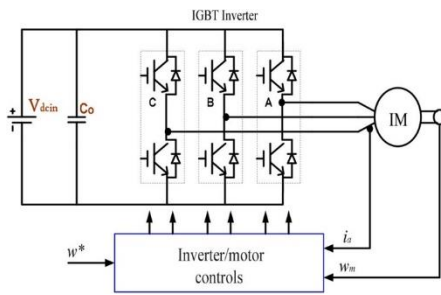

Figure 1 EV drive with an IM

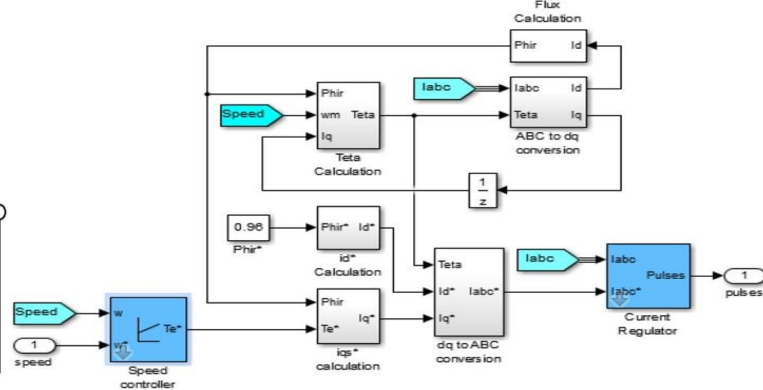

Figure 2 Control system of IM

The primary thing is reducing the value the drive cycle, at desired speeds and higher, and efficiency and the main strength. The performance of the inverter will suffer from the complete performance.

### 3 Control principle

#### 3.1 Traditional PID control

A PID controller is added in the circuit. In order to manipulate the velocity we have orientated Induction motor. From the figure 2 we can observe the conversion equations and a section which sets the rules and also gives the regulations. The conversion is taken place for currents. We can find the more additives of d and q by the below formulae.

$$\sin(\omega t) \sin \omega t - 223\pi \cos \sin \omega t \omega t + 223\pi \times i i s a s b s c (1) \cos(\omega t) \cos \omega t - \text{three}$$

The live and reactive energy calculated now consists of oscillation and common additives. However, The outer PID loops are utilised to gather the common components of the outputs. The active strength and reactive electricity. A block diagram of the conventional PID manipulate is given in fig.3. This PID produces

$$\begin{aligned} \text{active current reference (id*) and reactive modern-day reference (iq*), as given within the following conversions:} \\ \text{Id*} &= \text{kp(pref} - \text{p)} + \text{ki} \int (\text{pref} - \text{p}) dt \quad (2) \\ \text{Iq*} &= \text{kp(qref} - \text{q)} + \text{ki} \int (\text{qref} - \text{q}) dt \quad (\text{three}) \end{aligned}$$

Where  $k_p$  = proportional steady and  $k_i$  = simple constant. Pref = the energy reference and Qref = reference fee of the reactive power. The circuit is designed using the loop. While comparing with actual and current. Thus we can change the loops.

While the non-linear movements of the motors, the main SCIM controlling this hassle stays a tough hassle due to the fact many elements range with the real time conditions. The considerations of the design are Using fuzzy rules in specific locations, choosing the features and adjusting, deciding on scaling elements.

The losses of this are at full load. This is the max test we can run and the outputs are mentioned

## 4. Results and Discussions

The outputs for an average of 25 simulations. In this way the vehicles reached 9kw in 0.6s and when time is 12s the brakes are applied to 72%. This activates the motor to send the energy generated while applying brake to the battery and recharge the battery.

## 5. Conclusion

With the above experimentation we can conclude that when an induction motor runs in the nominal power or in less load. Then it consumes more power than needed. The extra energy consumed will generate heat. The inputs given to the controller are the errors generated which running or in the beginning of the time period. In this the simulation is conducted on a 50 horse power induction motor driven electric vehicle. With this the overall performance signs are tested inclusive of peak overshoot, regular-state blunders, upward push time, and settling time. The outcomes confirmed that the section present day inside the recommended machine includes less loss. The loss of amplitude are decreased for real torque inside the region. This gives us the torque with no errors and higher performance than the PID controller in all the aspects. The proposed design of the circuit is shown with the results which gives the best outcomes similar to the real time conditions.
